The discovery of a colossal magnetoresistance and magnetocaloric (MC) effects in hole-doped perovskite-type manganites of $R_{1-x}A_x'MnO_3$ (where $R$ and $A'$ are rare-earth and alkaline-earth metals, respectively) has generated significant interest in the solid-state physics community. The substitution of $A'$ for $R$ in these materials adds Mn$^{4+}$ ions, pre-existing Mn$^{3+}$ ions. This modifies the structural characterization and magnetic interactions of manganites. Among the studied hole-doped manganites, Pr$_{1-x}$Ca$_x$MnO$_3$ compounds are most promising because their electrical and magnetic properties at temperatures below the ferromagnetic-paramagnetic (FM-PM) phase transition ($T_C$) associated with double-exchange (DE) interactions between Mn$^{3+}$ and Mn$^{4+}$ ions are intriguing and sensitive to the variation of Ca content ($x$). For example, in the doping range $x=0.3$–0.5, Pr$_{1-x}$Ca$_x$MnO$_3$ compounds exhibit the charge-ordered anti-FM behavior, while the compounds with $0<x<0.3$ are a FM insulator. These features are quite different from lanthanum-manganite-based compounds, in which the FM phase is accompanied with metal-like behaviors. Moreover, AC susceptibility and magnetization for Pr$_{1-x}$Ca$_x$MnO$_3$ single crystals with $x=0.27$ and 0.29, exhibit nearly Heisenberg model exponents. Polycrystalline Pr$_{1-x}$Ca$_x$MnO$_3$ samples revealed coexistence of anti-FM/FM and spin-glass behaviors at low Ca-doping concentrations ($x=0.0$–0.2). The samples with higher Ca concentrations (e.g., $x=0.3$–0.5) exhibit the charge-ordered state. Particularly, in the range of $x=0.2$–0.3, the samples demonstrate a non-monotonic change of $T_C$, with the maximum value of $T_C$ achieved for $x=0.25$.

To further understand magnetic interactions in these compounds, we prepared polycrystalline Pr$_{1-x}$Ca$_x$MnO$_3$ samples with $x=0.25$, 0.27, and 0.29, and studied their critical behavior. FM interactions of the first two samples fall into the 3D-Heisenberg universality class, while those of the third ($x=0.29$) fall into the universality class of the mean-field theory. Additionally, the MC effect of these compounds is also taken into account.

Three polycrystalline samples Pr$_{1-x}$Ca$_x$MnO$_3$ with $x=0.25$, 0.27, and 0.29 were prepared from high-purity powders of Pr$_6$O$_{11}$, CaCO$_3$, and MnO (3N) using conventional solid-state reaction. The powders combined with stoichiometric quantities were mixed, ground carefully, and then pre-annealed at 1100°C for 24 h. After pre-annealing, the...
mixtures were re-ground, pressed into pellets, and sintered in air at 1300 °C for 48 h. An X-ray diffractometer (Brucker AXS, D8 Discover) was used to check the crystal structure of the final products. Room-temperature X-ray diffraction patterns revealed the samples exhibiting a single phase in an orthorhombic structure (space group: Pbnm). Magnetization measurements versus temperature and magnetic field were performed on a superconducting quantum interference device (SQUID) working at temperatures ranging from 5 to 350 K.

To study the influence of Ca doping on the magnetic properties of Pr$_{1-x}$Ca$_x$MnO$_3$, we measured temperature dependences of zero-field-cooled (ZFC) and field-cooled (FC) magnetizations, $M_{ZFC/FC}(T)$, for an applied field $H = 100$ Oe. The results shown in Fig. 1 indicate that with increasing temperature, $M_{ZFC}$ first increases and then reaches its maximum value (where magnetic energy of anisotropic fields generated from FM clusters/domains is equal to that of the external field $H = 100$ Oe). Increasing temperature above 110 K (for $x = 0.25$ and 0.27) and 90 K (for $x = 0.29$) rapidly reduces $M_{ZFC}$ values due to the FM-PM phase transition, in which the Mn$^{3+}$-Mn$^{4+}$ FM coupling is weakened by thermal activation energy. The $T_C$ values determined from the minima of $dM(T)/dT$ versus $T$ curves (see the insets of Fig. 1) are about 124 K, 118 K, and 110 K for $x = 0.25, 0.27$, and 0.29, respectively. It appears that $T_C$ slightly shifts towards lower temperatures when the Ca concentration in Pr$_{1-x}$Ca$_x$MnO$_3$ increases. This is because the substitution of Ca$^{2+}$ for Pr$^{3+}$ introduces more Mn$^{3+}$ ions, which enhance Mn$^{3+}$-Mn$^{4+}$ anti-FM interactions besides pre-existing Mn$^{3+}$-Mn$^{3+}$ anti-FM ones. The reinforcement of anti-FM interactions weakens Mn$^{3+}$-Mn$^{4+}$ FM interactions, and thus decreases the phase-transition temperature $T_C$. Specifically, the $M_{ZFC}$ and $M_{FC}$ branches bifurcated at $T = 118, 112,$ and 100 K for $x = 0.25, 0.27$, and 0.29, respectively. At $T = 5$ K, this deviation is about 10 emu/g, which gradually decreases at higher temperatures. This might be due to the existence of an anisotropic field generated by FM clusters. Magnetic moments of the Mn ions could be frozen in the directions favored energetically by their local anisotropy field or by an external field. It has also been suggested that this feature is related to the coexistence of FM and anti-FM phases and magnetic frustration existing in the samples.6

The present study focuses on the critical behavior of the Pr$_{1-x}$Ca$_x$MnO$_3$ samples. Figure 2 shows the $M(H)$ curves, and Arrott plots7 ($M^2$ versus $H/M$) at temperatures around the $T_C$ values. The $M(H)$ curves are typical for ferromagnets. Magnetization increases quickly at low-magnetic fields, and then increases slowly at fields $H > 10$ kOe. However, no saturation magnetization is achieved for all the $M(H)$ curves, even though high fields (up to 50 kOe) are used. This might be due to the existence of magnetic inhomogeneity or short-range FM order. Such the behaviors were also observed for Pr$_{0.5}$Ca$_{0.5}$MnO$_3$.8

The Arrott plots in Figs. 2(b), 2(d), 2(f) exhibit nonlinear $M^2/H$ parts in the low-field region, which are driven in two opposite directions due to the FM-PM phase separation. The inverse Arrott plots ($H/M$ versus $M^2$ curves, not shown here) have positive slopes. This assures that the samples undergo a second-order magnetic phase transition (SOPT), according to Banerjee’s criteria.7 For a ferromagnet with the SOPT, temperature dependences of the spontaneous magnetization ($M_s$), inverse initial susceptibility ($\chi_0^{-1}$), and critical isotherm at $T = T_C$ ($M$) obey asymptotic relations9

$$M_s(T) = M_0(-\varepsilon)^\beta, \quad \varepsilon < 0,$$  

$$\chi_0^{-1}(T) = (h_0/M_0)\varepsilon^{\gamma}, \quad \varepsilon > 0,$$  

$$M = DH^{1/\delta}, \quad \varepsilon = 0,$$  

where $\varepsilon = (T - T_C)/T_C$ is the reduced temperature, $M_0, h_0, M_0,$ and $D$ are the critical amplitudes, $\beta, \gamma,$ and $\delta$ are the critical exponents associated with $M_s, \chi_0^{-1},$ and $M,$ respectively. The exponents $\beta$ and $\gamma$ quantify the growth of ordered moments at $T < T_C$ and the divergence of the magnetic susceptibility at $T > T_C,$ respectively.10 We used Eqs. (1) and (2), and the static-scaling equation of state ($H/M_2^1 = a + bM^{1+\beta}$ where $a$ and $b$ are temperature-dependent parameters) to determine values of $\beta$ and $\gamma$ (this approach is known as the modified Arrott plots).9 According to this method, correct values of $\beta$ and $\gamma$ results in the $M^{1+\beta}$ versus $H/M_2^1$ curves that are straight and parallel to each other in the vicinity of $T_C.$ The $M_s(T)$ and $\chi_0^{-1}(T)$ data are determined from the intersections of $M_{ZFC/FC}(T)$ curves for Pr$_{1-x}$Ca$_x$MnO$_3$ with (a) and (b) $x = 0.25;$ (c) and (d) $x = 0.27;$ and (e) and (f) $x = 0.29.$

**FIG. 1.** $M_{ZFC/FC}(T)$ curves for Pr$_{1-x}$Ca$_x$MnO$_3$ with $x = 0.25, 0.27,$ and 0.29 in the field $H = 100$ Oe.

**FIG. 2.** $M(H)$ curves and Arrott plots ($M^2$ versus $H/M$) for Pr$_{1-x}$Ca$_x$MnO$_3$ with (a) and (b) $x = 0.25;$ (c) and (d) $x = 0.27;$ and (e) and (f) $x = 0.29.$
linear extrapolations at high-magnetic fields with the $M/H$ and $(H/M)^{1/2}$ axes, respectively. Thus determined $M_s(T)$ and $\chi_0^{-1}(T)$ data are then fitted to Eqs. (1) and (2), respectively, to improve the estimates of $\beta$, $\gamma$, and $T_C$. New values of these critical parameters are subsequently re-used in next modified Arrott plots. This process is repeated until the $\beta$, $\gamma$, and $T_C$ values converge to stable ones. This procedure yields $T_C \approx 118$ K, $\beta = 0.351 \pm 0.003$, and $\gamma = 1.372 \pm 0.002$ for $x = 0.25$; $T_C \approx 116$ K, $\beta = 0.362 \pm 0.002$, and $\gamma = 1.132 \pm 0.004$ for $x = 0.27$; and $T_C \approx 110$ K, $\beta = 0.521 \pm 0.002$, and $\gamma = 0.912 \pm 0.005$ for $x = 0.29$. The results of the best fitting are shown in Fig. 3.

The critical exponent $\delta$ is determined by fitting the critical isotherm $M$ at the critical temperature $T_C$ to Eq. (3). Its values are $4.90 \pm 0.02$, $4.09 \pm 0.03$, and $2.71 \pm 0.02$ for the samples with $x = 0.25$, $0.27$, and $0.29$, respectively. These values are close to those obtained by using the Widom scaling relation $\delta = 1 + \gamma/\beta$ (4.91, 4.12, and 2.76 for $x = 0.25, 0.27$, and $0.29$, respectively).

The scaling law$^{11}$ stipulates that $M(H, T)$ in the vicinity of $T_C$ obey the scaling expression $M(H, e) = |e|^{\beta z} (H/|e|)^{(1+\gamma)}$, where $f_e$ and $f_\gamma$ are analytic functions associated with temperatures above and below $T_C$, respectively. This equation implies that with correct $\beta$ and $\gamma$ values, the $M/|e|^{\beta z}$ versus $H/|e|^{(1+\gamma)}$ data fall into two universal branches, one for temperatures $T > T_C$ and the other for $T < T_C$. Figure 4 shows that the $M(H, T)$ data for all samples, plotted in linear and logarithmic scales, fall into two universal curves for $T < T_C$ and $T > T_C$. This demonstrates that the obtained critical values are reliable and support the scaling hypothesis. It should be noticed that both the modified Arrott plots method and the scaling law work well for high-magnetic fields ($H > 10$ kOe). Their performance deteriorates in low-field regions because of the rearrangement of magnetic domains and uncertainty in the calculation of demagnetization factor.$^{12}$

The critical values determined from our Pr$_{1-x}$Ca$_x$MnO$_3$ samples, theoretical models,$^{13,14}$ and similar materials are listed in Table I. The critical exponent values for the $x = 0.25$ and $0.27$ samples are close to those expected for the 3D-Heisenberg model. Meanwhile, those for $x = 0.29$ are close to the mean-field theory. Similar behavior was found in some compounds studied previously, such as Pr$_{1-x}$Ca$_x$MnO$_3$ compounds with $x = 0.27$ and $0.29$, and Pr$_{0.77}$Pb$_{0.23}$MnO$_3$. This demonstrates the presence of a short-range FM order in the $x = 0.25$ and $0.27$ samples, and a long-range FM order in the $x = 0.29$ sample.

In addition to the critical behavior of the Pr$_{1-x}$Ca$_x$MnO$_3$ samples, we also analyzed their MC effect by studying magnetic-entropy change ($\Delta S_m$) as a function of temperature and magnetic field. With ferromagnets undergoing the SOPT, $\Delta S_m$ can be calculated from the Maxwell relation as$^{16}$

$$\Delta S_m(T, H) = \int_0^H \left( \frac{\partial M}{\partial T} \right)_H \, dH,$$  \hspace{1cm} (4)

where $H$ is the applied field. According to Eq. (4), the magnitude of $\Delta S_m$ depends not only on the magnitude of the magnetization $M$, but also on $(\partial M/\partial T)_H$. Since $(\partial M/\partial T)_H$ is related to magnetic ordering transition, a sharp change in the $M(T)$ curve at the FM-PM phase transition leads to a large $\Delta S_m$ value.$^{17}$ Figure 5(a) shows the $\Delta S_m(T)$ curves for the Pr$_{1-x}$Ca$_x$MnO$_3$ samples in an applied-field interval $\Delta H = 50$ kOe. A maximum
TABLE I. Comparison of critical exponents of our Pr$_{1-x}$Ca$_x$MnO$_3$ compounds with different theoretical models, as well as other materials (MAP = modified Arrott plot and KF = Kouvel-Fisher method).

Figure 5(b) shows that the dependence of $|\Delta S_{\text{max}}|$ on magnetic field $H$ can be described by a power law $|\Delta S_{\text{max}}| \propto H^n$, where $n$ is a magnetic-ordering parameter. The $n$ values are about 0.68, 0.71, and 0.74 for the $x = 0.25, 0.27$, and 0.29 samples, respectively. These values are close to those ($n = 0.61, 0.60,$ and $0.66$ for $x = 0.25, 0.27,$ and 0.29, respectively) calculated from the relation $n = 1 + (\beta - 1)/(\beta + \gamma)$ proposed by Franco et al. Accounting for the full-width-at-half maximum of the $|\Delta S_n(T)|$ curve (denoted as $\delta T_{\text{FWHM}}$) allows one to calculate the relative cooling power (RCP) from the relation $\text{RCP} = |\Delta S_{\text{max}}| \times \delta T_{\text{FWHM}}$. For $\Delta H = 50$ kOe, $\delta T_{\text{FWHM}}$ values are about 67, 71, and 85 K, leading to the RCP values of about 335, 290, and 215 J kg$^{-1}$ for $x = 0.25, 0.27$, and 0.29, respectively. These RCP values are comparable to those determined from some perovskite manganites.

The critical behavior and MC effect of Pr$_{1-x}$Ca$_x$MnO$_3$ ($x = 0.25, 0.27,$ and 0.29) are investigated. With the values of critical parameters obtained by using the modified Arrott plot, the $M(H, T)$ point data fall into two universal branches characterized by temperatures below and above $T_C$. The critical-exponent values of the Pr$_{1-x}$Ca$_x$MnO$_3$ samples with $x = 0.25$ and 0.27 are consistent with predictions of a nearest-neighbor 3D-Heisenberg model for short-range FM interactions. The critical-exponent values of the $x = 0.29$ sample are close to those predicted by the mean-field theory for long-range FM interactions. Around $T_C$, field dependences of $|\Delta S_{\text{max}}|$ can be described by a power law $|\Delta S_{\text{max}}| \propto H^n$. The $n$ values ($n = 0.68–0.74$) obtained from the power-law fitting are close to those ($n = 0.61, 0.60,$ and 0.66) calculated from the theoretical relation $n = 1 + (\beta - 1)/(\beta + \gamma)$. Under an applied-field change of $\Delta H = 50$ kOe, $|\Delta S_{\text{max}}|$ is approximately 5.0, 4.1, and 2.5 J kg$^{-1}$ K$^{-1}$, corresponding to RCP values of about 335, 290, and 215 J kg$^{-1}$ for the $x = 0.25, 0.27$, and 0.29 samples, respectively.
